

Intracranial meningioma metastatic to the lung

James K. Stoller, MD

Although meningiomas only rarely metastasize, extracranial metastasis does occur and the lung is the most common site. To clarify the clinical spectrum of metastatic meningioma and to highlight its importance for the pulmonary physician, the authors describe one case and review 112 others. Metastatic meningioma should be considered in the differential diagnosis of the solitary pulmonary nodule, especially in patients with an associated intracranial mass.

Index terms: Case reports • Lung neoplasms, metastases • Meningioma

Cleve Clin J Med 1987; 54:521-527

Although meningiomas usually are benign intracranial tumors, unusual clinical presentations may occur, such as extracranial primary meningiomas^{1,2} (including primary lung tumors³), or extracranial metastases from intracranial primary tumors.⁴⁻⁶ Metastatic meningiomas are rare,^{4,7-9} as only 112 cases have been described since the first report by Power in 1886.¹⁰ We recently encountered a patient whose intracranial meningioma metastasized to the lung.

Case report

A 63-year-old woman with a history of locally recurrent meningioma presented to the Cleveland Clinic in September 1986 for evaluation of lower abdominal discomfort. During an evaluation for syncope in 1968, she had a left frontal intracranial mass, which was completely resected and identified as a meningioma (fibroblastic type). Histologic examination showed dural invasion. In 1976, a recurrent left frontal meningioma was detected after a focal right-sided seizure, and the patient underwent a second craniotomy and resection. The recurrent meningioma (transitional type) (*Fig. 1*) was adjacent to the sagittal sinus and again invaded the dura. As with the original tumor, there was no histologic evidence of necrosis, mitosis, or invasion of the cerebral cortex. Neither tumor exhibited features of a papillary or hemangiopericytoma pattern.^{11,12} The patient had since been free of seizures. She continued to smoke two packs of cigarettes daily as she had for 20 years.

In 1986, however, the patient complained of abdominal pain. Physical examination revealed mild, diffuse, lower abdominal tenderness, but was otherwise unremarkable. A computed tomogram of the abdomen showed a left lower-lobe lung nodule that was not apparent on the plain chest radiograph (*Fig. 2*). Further evaluation with chest CT and densitometry studies revealed a single 13-mm noncalcified nodule. The patient underwent a mediastinoscopy and subsequent thoracotomy with left lower-lobe wedge resection. Bronchial and mediastinal lymph nodes showed no evidence of tumor. Histologic examination of the nodule (*Fig. 3*) revealed a meningioma with features similar to the patient's recurrent intracranial lesion. After an uneventful postoperative recovery, additional workup with CT of the head revealed a 2.5-cm left frontal lesion, interpreted as a third local recurrence.

Discussion

Lung metastasis from intracranial meningioma

Fig. 1. A. Meningioma (second recurrence). The cells are arranged in whorls and palisades typical of meningioma. (Hematoxylin-eosin, $\times 340$)

B. Meningioma (second recurrence). Prominent intranuclear pseudo-inclusions are present. (Hematoxylin-eosin, $\times 340$)

Fig. 2. CT scan of the abdomen, showing left lower lobe nodule.

Fig. 3. A. Meningioma metastatic to the lung. The histologic pattern and intranuclear pseudoinclusions are similar to the recurrent intracranial meningioma resected 10 years earlier. (Compare with Fig. 2.) (Hematoxylin-eosin, $\times 340$)

B. Meningioma metastatic to the lung. High-power magnification demonstrates whorls and nests typical of meningioma. (Hematoxylin-eosin, $\times 540$).

is rare and has received little attention in the pulmonary literature. The case report described here establishes metastatic meningioma among the causes of solitary pulmonary nodules, especially in patients with associated intracranial masses. To further clarify the clinical spectrum of metastasizing meningioma, we reviewed the 113 available case descriptions of meningiomas that have metastasized to extracranial sites. A total of 88 cases have already been reviewed,^{5,13} but eight more have been reported since and 17 others were not included in the earlier series. *Table 1* presents the clinical features of these 25 additional patients.

Table 2 lists the metastatic sites in all 113 patients (mean, 1.9 metastases per patient). Although most patients (52%) had single metastases, multiple metastases were common (*Fig. 4*), with two metastases in 26%, three in 8%, and more than three in 13%. (The greatest number of metastases reported in a single patient is 11.³¹) Altogether, 61% of the 113 patients had lung metastasis (with or without others) and, as in our newly reported patient, the lung was the only site of extracranial metastasis in 32%. However, it was nearly as common (31%) for metastases to spare the lung but involve other extracranial organs. Only rarely were the pulmonary metas-

Liver	29	13
Reticuloendothelial system (e.g., lymph nodes, spleen)	25	11
Kidney	18	8
Other site	37	16
TOTAL	225	100

Fig. 4. Number of metastases in patients with metastatic meningioma.

tases associated with local symptoms (e.g., dyspnea, pleuritic pain, and in two extraordinary cases, respiratory failure^{19,32}). Most lung metastases were incidentally detected by chest radiography or by CT (53%). In the case we just described, the metastasis occupied a costophrenic sulcus and therefore escaped detection by plain chest radiography. Lung metastases were sometimes first detected at necropsy (37% of patients).

Although varying clinical surveillance makes it difficult to assess the interval between the primary and detection of the first metastasis, the literature collectively suggests that metastatic meningioma is usually an indolent disease. In 22 of 25 recently described patients for whom such information is available, the mean (\pm SD) interval from detection of the primary tumor to detection of the first metastasis was 77 months (6.4 years) \pm 66 months, and the longest interval was 20 years. Among all 113 cases, the longest reported interval to first detection of metastases is 24 years.⁵ Mean survival time from first diagnosis to death in recently reported patients was 88 months (range, one month to 19 years). Death may result from sequelae of distant metastases or, more frequently, from local intracranial recurrence, which has been estimated to occur in 10%–21% of patients with metastatic meningioma.^{7,8}

Because metastasis is especially surprising when the primary meningioma is histologically benign, investigators have suggested two risk factors for extracranial spread: previous craniotomy and venous sinus invasion. Yet neither factor explains all observed metastases. Specifically, Simpson⁸ observed histologic infiltration of venous sinuses in 34 of 246 (14%) patients with intracranial meningioma, though only one of the patients had detectable extracranial metastases. Kepes¹³ observed that more patients with extracranial metastases had previously undergone craniotomy (59 patients *v.* 13 patients), but Shaungshoti et al⁶ reported that 25% of patients with extracranial metastases had *not* previously undergone resection, including those whose tumors did not grossly infiltrate venous sinuses. Thus, although hematogenous dissemination is a likely mechanism, the exact cause of extracranial metastasis remains equivocal.
