Mucormycosis presenting as dental pain

Figure 1. Multiple tracts in the buccal vestibule were noted on the left gum. The arrow indicates the most medial tract.

A 19-YEAR-OLD INDIAN FEMALE WAS referred to the emergency department by her dentist. She had presented to the dentist with 15 days of constant pain in the left premolar tooth, describing the pain 8 out of 10 and radiating to the left cheek. The dentist performed a root canal procedure, which did not resolve the pain, and 1 week after the procedure she developed mobility in her left upper teeth and sinus discharges on the upper buccal mucosa.

On presentation in the emergency department, the patient said that she had recovered from COVID-19 about 2 weeks earlier and had been treated with dexamethasone. Evaluation in the emergency department showed that she was hemodynamically stable and afebrile. The left side of her face was tender to palpation. On oral examination, mobility of the left upper teeth was noted, with purulent discharge on the upper buccal mucosa (Figure 1).

Figure 2. Markedly inflamed and hypertrophic mucosa of the left maxillary sinus cavity were noted on magnetic resonance imaging. The arrows point to the lateral and inferior sides of the left maxillary sinus.

Results of a complete blood cell count and basal metabolic panel were unremarkable. Magnetic resonance imaging with contrast revealed markedly

inflamed and hypertrophic mucosa of the left maxillary sinus cavity (Figure 2). The left maxillary bone was noted to be necrotic and nonenhancing (Figure 3). The findings on oral examination and imaging raised concern for mucormycosis, and the patient was referred for emergency surgery.

She underwent thorough debridement and left subtotal maxillectomy. Intraoperatively, the left maxillary sinus cavity could be seen to communicate with the buccal vestibule (**Figure 4**). Microscopic examination of the excised tissue demonstrated hyphae of irregular width and branching angles of 90 degrees. A diagnosis of maxillary mucormycosis invading into the buccal vestibule was made. The patient was started on amphotericin B, and at 4 weeks after surgery, she had improved completely.

MUCORMYCOSIS: SYMPTOMS, DIAGNOSIS, AND TREATMENT

Mucormycosis is an infection caused by filamentous molds that commonly affect immunocompromised patients such as those with cancer or uncontrolled diabetes.¹ In 2021, a systematic review found numerous cases of invasive fungal infection and mucormycosis reported in patients with COVID-19.² This has been attributed to diabetes as a common predisposing comorbidity and to treatment with steroids. Our patient was healthy at baseline. We believe that her

Figure 4. Communication between the buccal vestibule and the maxillary sinuses (arrow) was noted on intraoperative evaluation.

treatment with steroids and her immunocompromised state secondary to COVID-19 may have predisposed her to mucormycosis.

Our patient had initial symptoms 25 days after COVID-19 infection, which aligns with the already available literature.³ Several hospitals in India have opened outpatient departments for mucormycosis to monitor COVID-19-recovered patients from 10 days to 6 weeks, when they are most vulnerable to the fungal infection.³

Symptoms

Initial symptoms of mucormycosis are paresthesia and swelling over the face, nasal congestion and discharge, fever, headache, and lethargy, which are similar to symptoms of sinusitis and periorbital cellulitis. However, the appearance of black lesions on the nasal bridge or upper inside of the mouth that are progressively increasing in number or size and associated pulmonary symptoms like cough, chest pain, and dyspnea in a patient with diabetes or immunosuppression should raise a strong suspicion for maxillary mucormycosis. Nevertheless, in rare cases, dental pain can also be a presenting feature of maxillary mucormycosis.4 As this disease is rapidly progressive, early diagnosis is crucial in the prognosis of the patient. Fortunately, our patient's dentist was able to recognize this alarming sign on the second visit and transfer the patient for an emergency evaluation.

Diagnosis and treatment

Microscopic examination of excised tissue in mucormycosis shows hyphae of irregular width and branching angles of 90 degrees. On histopathology, the invasive disease is characterized by prominent infarcts and angioinvasion. Rapid identification of invasive mucormycosis is necessary to minimize the mortality and morbidity of this disease. Thus, it is worthwhile for clinicians to be able to rapidly identify the characteristics of hyphae of mucormycosis.

It is pertinent to mention that mucormycosis is not contagious. A person can get mucormycosis through contact with fungal spores in the environment. For example, the lung or sinus forms of the infection can occur after someone inhales spores from the air.

Treatment includes immediate hospitalization, surgical debridement and systemic antifungal therapy. The liposomal formulation of amphotericin B (AmBisome) is the drug of choice based on efficacy and safety data.

■ TAKE-HOME MESSAGE

Our patient's case illustrates the need for early diagnosis and urgent debridement for better outcomes. Mucormycosis should be considered in the differential diagnosis for any patient presenting with dental pain in the setting of recent COVID-19 infection.

DISCLOSURES

The authors report no relevant financial relationships which, in the context of their contributions, could be perceived as a potential conflict of interest.
