Male and female pattern hair loss: Treatable and worth treating

ABSTRACT

Pattern hair loss is the most common type of hair loss in both men and women. Scalp hair is typically affected in a characteristic distribution without other scalp or dermatologic findings. Early recognition and treatment can help halt its progression to preserve as much hair as possible. Both pharmacologic and nonpharmacologic treatments have proven helpful.

KEY POINTS

Male and female pattern hair loss is a nonscarring, progressive form of alopecia that typically affects the temporal, frontal, and vertex scalp in men and central scalp in women.

The process can begin soon after puberty, and the resulting hair loss negatively affects quality of life and self-image.

Pattern hair loss is commonly diagnosed with a thorough history; physical examination of the face, scalp, and nails; the hair-pull test; dermoscopy; and laboratory testing. A hair biopsy may be of value for clinically challenging cases.

Topical minoxidil and oral finasteride are first-line treatments for male pattern hair loss and topical minoxidil is the first-line therapy for female pattern hair loss, but there are a number of other off-label pharmacologic and nonpharmacologic treatments.

PATTERN HAIR LOSS is a progressive, non-scarring form of hair loss characterized by gradual loss of terminal hair and follicular miniaturization to vellus hair fibers on the scalp in a characteristic distribution. It is the most common form of hair loss in both men and women and has psychosocial effects, including stress and diminished quality of life.

This review focuses on clinical presentation, diagnosis, and treatment of pattern hair loss.

MANY NAMES FOR IT

This condition goes by many names, such as androgenetic alopecia, androgenic alopecia, male balding, male pattern hair loss, female pattern alopecia, diffuse alopecia in women, and hereditary alopecia. The term “androgenetic alopecia” was used in the past, recognizing the hormonal and hereditary influences underlying the condition in men.

As our understanding of both the pathophysiology and phenotypic expression expanded, so did the collection of terms used to identify this disorder. Newer terminology developed to express the different patterns of presentation in men and women and the uncertain role, and frequent absence, of androgen excess in women. Male pattern hair loss and female pattern hair loss are now the favored terms.

GENES PLAY A ROLE

Male and female pattern hair loss are polygenic conditions, which explains their high prevalence and variable phenotypic expression. Epigenetic modifications may alter genetic susceptibility.

Interestingly, genetic variations associated with the androgen receptor gene (AR) have
HAIR LOSS

been linked to development of male pattern hair loss, but genes for aromatase (CYP19A1), estrogen receptor-a (ESR1), type I 5-alpha reductase (SRD5A1), and insulin-like growth factor 2 (IGF-2) do not have any established association with it.1

Research into genetic associations with female pattern hair loss is less extensive and robust than that of male pattern hair loss. Studying the relationship between female pattern hair loss and AR has proven difficult, since AR is located on the X chromosome, which undergoes X inactivation in women.1 An allelic variant of CYP19A1 was associated with a predisposition to female pattern hair loss in a genome-wide association study.2

LINKED TO ANDROGEN EXCESS IN MEN

Androgens are considered necessary for male pattern hair loss to develop. The condition typically begins after the start of puberty, which is marked by a striking increase in androgen levels. Dihydroxytestosterone, a potent metabolite of testosterone synthesized in a reaction catalyzed by 5-alpha reductase in the peripheral target organs, hair follicle, and sebaceous glands, plays a role in normal hair growth and male pattern hair loss development in androgen-sensitive areas such as the vertex and frontal scalp, beard, axilla, pubis, and extremities. Dihydroxytestosterone assists normal hair growth in these areas, but elevated cellular levels of androgen receptors and 5-alpha reductase3 and increased production of dihydroxytestosterone4 have been documented in cases of male pattern hair loss. No cases of male pattern hair loss have been documented in men with 5-alpha reductase deficiencies.5

UNCLEAR RELATIONSHIP WITH HORMONES IN WOMEN

The relationship between androgens and female pattern hair loss is less clear. Female pattern hair loss has been observed in women with high androgen levels,6 but it has also been documented in a patient with complete androgen insensitivity syndrome.7 Additionally, most women with female pattern hair loss have normal testosterone levels and lack clinical manifestations of hyperandrogenemia.6

The role of circulating estrogens in the development of female pattern hair loss is also unclear. The prevalence of hair loss increases after menopause. Evidence is conflicting regarding whether estrogen stimulates or inhibits the hair follicle.1

CAN BEGIN EARLY

Pattern hair loss in men and women begins soon after puberty. Thinning of hair and non-scarring loss of terminal hairs, resulting in a decrease in hair density, generally progress slowly over years. The scalp is healthy without associated symptoms.

In men, hair loss typically affects the central scalp, including the midfrontal, temporal, and vertex regions (Figure 1). The 7-stage Hamilton-Norwood scale is commonly used.
to classify male pattern hair loss. However, in some men, hair loss does not follow this typical progression or is more severe in particular areas.

In women, the characteristic distribution of hair loss is different. Female pattern hair loss has 2 general distributions: diffuse thinning across the central scalp and the characteristic “Christmas tree” pattern observed along the midline part of the hair due to prominent hair thinning towards the front of the scalp with minimal involvement of the hairline (Figure 2). The frontal hairline is less likely to be involved, but bitemporal thinning is common. The 3-grade Ludwig scale is commonly used to characterize female pattern hair loss.

**A CLINICAL DIAGNOSIS**

Pattern hair loss is typically diagnosed clinically (Table 1).

**History**

A thorough history should be elicited, including age of onset of hair loss, time course, severity, hair loss distribution, progression (ie, periods of shedding), and accompanying symptoms. For women, a gynecologic history may help uncover an underlying cause such as polycystic ovarian syndrome or hyperandrogenism. The patient should be asked about any family history of hair loss, metabolic syndromes (eg, diabetes mellitus), and androgen excess; medications; and medical history.

Conditions that worsen hair loss, including iron deficiency, thyroid dysfunction, and nutritional deficiencies, should be considered and managed to improve treatment results.

**Physical examination**

A complete skin evaluation should be conducted, including the face, scalp, and nails.

When examining the scalp, note the distribution of hair loss, the caliber of hairs, and other clinical features. Male pattern hair loss typically presents as a receding hairline and hair miniaturization on the frontal and vertex scalp. In women, the vertex and midfrontal scalp are commonly affected, as described above. Hair loss can be assessed by comparing the hair part of the central scalp with that of the occipital scalp, which is generally spared. Hair miniaturization can be seen better using a sheet of paper as a backdrop and comparing the caliber of adjacent hair shafts.

Inflammation, scarring, or scaling of the scalp suggests a different diagnosis, as pattern hair loss is usually unaccompanied by these signs. Nevertheless, seborrheic dermatitis is more prevalent in people with pattern hair loss, so male and female pattern hair loss can present with another scalp condition. Seborrheic dermatitis is often associated with seborrhea (oily scalp) which is a result of androgen stimulation of the sebaceous glands.

Nail involvement (eg, pitting, trachyonychia, and longitudinal ridging) and patchy hair loss in nonscalp regions (eg, the eyebrows) are inconsistent with the diagnosis of male or female pattern hair loss.

**Hair-pull test**

The hair-pull test, which is useful in detecting active hair loss, is performed by grasping 50 to 60 hairs close to the scalp with the thumb, index, and middle fingers and slowly pulling. If 6 or more hairs come loose, hair loss is likely active.

Extracted hair can be examined under the microscope to characterize the type (eg, broken or dystrophic) and the phase (eg, telogen [resting] or anagen [growth]). A study by McDonald et al suggested that neither washing nor brushing the hair affects results of the hair-pull test. In pattern hair loss, the hair-pull test is generally negative, though it can be positive early in the process on the vertex or midfrontal scalp.
Dermoscopy
Examination of the scalp with a dermatoscope can reveal epidermal and dermal structures undetectable with the naked eye. Dermoscopic findings of diversity in hair diameter, yellow dots (sebaceous glands), perifollicular pigmentation, and lack of scarring are consistent with the diagnosis of male or female pattern hair loss. Small focal areas with complete hair loss may be observed, and skin pigmentation in these areas may vary due to sun exposure.

Scalp biopsy
Though generally not required, a scalp biopsy can be helpful when the clinical picture is unclear or coexisting scalp conditions are suspected. Two 4-mm punch biopsies are taken in the direction of the hair shaft, allowing for transverse and vertical sectioning.

Histologic features of male and female pattern hair loss include terminal hair miniaturization (hair shaft diameter ≤ 0.03 mm), increased percentage of telogen hairs (15%–20%), decreased ratio of terminal to vellus or vellus-like hairs (1.9:1 in men and 1.5:1 in women), and reduced total number of hairs per unit area.

Laboratory testing
Thyroid-stimulating hormone and iron studies (including serum ferritin, serum iron, and total iron binding capacity) can be helpful in assessing men and women with pattern hair loss.

Women with clinical manifestations of androgen excess such as hirsutism, adult acne, irregular menses, and acanthosis nigricans should undergo a laboratory workup for hyperandrogenemia. This includes free or total testosterone with or without dehydroepiandrosterone sulfate. Measuring serum prolactin can also be considered for women presenting with concomitant galactorrhea or elevated testosterone.

A complete blood cell count and comprehensive metabolic panel are also routinely done. Because many people are on restricted diets, a nutrient screen is suggested that includes iron saturation, ferritin, zinc, and vitamin D levels.

Differential diagnosis
Other forms of alopecia that may present similarly to male and female pattern hair loss include telogen effluvium, alopecia areata, traction alopecia, trichotillomania, central centrifugal cicatricial alopecia, lichen planopilaris, and frontal fibrosing alopecia (Figure 3).

Telogen effluvium, a condition of non-inflammatory, diffuse hair loss, is often difficult to distinguish from female pattern hair loss. A thorough history is very important, as there is generally an inciting trigger such as psychological stress, childbirth, weight loss, or medications (eg, interferons, antihyperlipidemic medications, derivatives of retinol, anticoagulants) that precedes telogen effluvium by a few months. Hair loss generally occurs over the entire scalp, occasionally most prominently in the temporal areas. The hair-pull test is positive, with increased shedding of telogen hairs when telogen effluvium is active. Of note, telogen effluvium and female pattern hair loss can coexist in the same patient.

Alopecia areata commonly presents as focal, smooth patches of hair loss, which spontaneously regrow (Figure 3A). Rarely, it can present as diffuse hair loss with widespread decreased hair density (diffuse alopecia areata) or as larger patches of hair loss on the frontal, parietal, and temporal scalp (ophiasis inversus), mimicking female and male pattern hair loss, respectively. Alopecia areata totalis and alopecia areata universalis are characterized by more severe hair loss; alopecia areata totalis represents total loss of scalp hair, whereas alopecia universalis has more extensive hair loss including the face and body in addition to the scalp (Figure 3B).

The onset is usually sudden with prominent shedding, characteristically an anagen effluvium with dystrophic anagen hairs. Telogen hairs are typically lost during chronic shedding. These patients commonly have a positive family history of alopecia areata. Additionally, nail involvement, such as pitting, longitudinal fissuring, and lunula reddening, occur in 10% to 20% of patients with alopecia areata. The hair-pull test is positive in patients who are actively shedding.

Traction alopecia is a result of chronic (prolonged or repeated) tension on the hair, often from hairstyles. Hair loss along the hairline is common (Figure 3C). A thorough his-
Trichotillomania is a psychiatric condition in which patients repeatedly pull at their hair. Hair loss can occur on different portions of the body with hairs of different lengths as a result of episodes of hair pulling or variations in breakage point along the hair shaft within the same episode. Hair loss occurs in bizarre patterns (Figure 3D). The eyebrows, eyelashes, and pubic hair can be involved.

Central centrifugal cicatricial alopecia, most commonly affecting women of African descent, is a form of scarring alopecia that often affects the vertex of the scalp. It is associated with the gene PAD13, which encodes an enzyme, type III peptidyl arginine deiminase, critical for hair shaft formation.19 Usually, central centrifugal cicatricial alopecia first presents as a patch of hair thinning that progresses to more severe hair loss expanding from the center of the lesion. It increases in size in a centrifugal fashion, with the center most severely affected with loss of hair follicles (Figure 3E). Central centrifugal cicatricial alopecia can be differentiated from female pattern hair loss by visible loss of the follicular ostia. Additionally, it can present with other signs and symptoms on the scalp, including pustules, erythema, tenderness, and pruritus.

Lichen planopilaris and frontal fibrosing alopecia are uncommon inflammatory scarring alopecias that have similar histologic findings but dissimilar clinical presentations. Classic lichen planopilaris presents as small to large areas of patchy hair loss, frequently affecting the vertex or parietal scalp (Figure 3F). Hair loss in lichen planopilaris may present similarly to central centrifugal cicatricial alopecia, but there are no vellus hairs in lichen planopilaris.20 Nail, cutaneous, and mucosal involvement can occur.

Frontal fibrosing alopecia results in recession of the hairline in a bandlike distribution in women (Figure 3G), with perifollicular erythema, and follicular hyperkeratosis. Unlike female pattern hair loss, frontal fibrosing alo-
HAIR LOSS

HAIR LOSS

pecia often affects the eyebrows and temporal scalp and can result in complete and permanent hair loss.

■ LOWER SELF-ESTEEM

Pattern hair loss can lead to negative feelings in both men and women and can contribute to stress, decrease body image satisfaction, damage self-esteem, and diminish quality of life, especially among women and individuals seeking treatment.21 Patient and physician perceptions of disease severity may diverge, underlying the importance of attending to the psychosocial and psychoemotional status of these patients.22

■ LOSS IS PROGRESSIVE

Pattern hair loss is progressive, leaving patients with diminished hair density. Male pattern hair loss can result in complete loss of hair coverage in particular areas, whereas female pattern hair loss rarely advances to baldness.

Response to pharmacologic treatment varies, but it is important to recognize pattern hair loss and initiate treatment early in the disease process to try to prevent further hair loss and promote some degree of hair regrowth.

■ TREATMENT

The goal of treatment of pattern hair loss is to promote regrowth of hair to improve scalp coverage and to prevent or slow further hair thinning and loss. Topical minoxidil and oral finasteride are the first-line treatments for male pattern hair loss, and topical minoxidil is the first-line treatment for female pattern hair loss. However, there are a number of alternatives. Detecting and treating comorbidities such as androgen excess and nutritional deficiencies is helpful in maintaining hair growth.

Minoxidil

Mechanism of action. Through an unclear mechanism, minoxidil enhances hair growth by enlarging miniaturized hair follicles, extending anagen, and shortening telogen.23

US Food and Drug Administration (FDA) approval. Minoxidil is FDA-approved for treating both male and female pattern hair loss.

Administration. Topical minoxidil is available over the counter in 2% and 5% solutions and 5% foam in the United States. Patients should apply 1 mL of 5% solution or half a cap of 5% foam once a day directly to involved areas of the scalp (not the hair) when dry. Treatment should be assessed for efficacy after 1 year of use, but results may be observed sooner.

Efficacy in men. In a 48-week, double-blind, placebo-controlled, randomized trial, 5% minoxidil solution was superior to 2% solution in terms of patient perception of hair growth and treatment benefit, investigator perception of hair growth, and nonvellus hair count.24 Response time was also shorter with the 5% solution. Both the 2% and the 5% topical minoxidil solutions were superior to placebo.

Foam has not been directly compared with liquid solutions. Compared with placebo, 5% minoxidil foam increased the hair count and improved hair loss as assessed by the patient

on August 30, 2022. For personal use only. All other uses require permission.
and physician. Individual response to treatment with minoxidil varies, and hair regrowth can be lost after stopping.

**Efficacy in women.** A meta-analysis found that topical minoxidil was effective and safe for treating female pattern hair loss, with no significant difference in efficacy and safety between different concentrations. Topical minoxidil is an effective treatment for women regardless of androgen status and age.

**Side effects.** Minoxidil stimulates telogen follicles to enter anagen, so transient hair shedding may occur when initiating therapy. Contact dermatitis and hypertrichosis are common side effects. Compared with 2% topical minoxidil, 5% preparations are more likely to cause local pruritus and irritation.

### Finasteride

**Mechanism of action.** Finasteride, a competitive inhibitor of type II 5-alpha reductase, decreases production of dihydroxytestosterone. Oral finasteride reduces scalp dihydroxytestosterone levels by approximately 60% to 70%, depending on the dosage.

**FDA approval.** Finasteride is FDA-approved for treating male pattern hair loss, but not female pattern hair loss.

**Administration.** Men with male pattern hair loss can be treated with finasteride 1 mg daily. Treatment should be assessed for efficacy after 1 year of use, but results may be observed sooner.

**Efficacy in men.** Finasteride has been shown to increase the hair count, physician-assessed hair coverage, and hair mass compared with placebo.

A systematic review of the efficacy of finasteride in men with male pattern hair loss found finasteride 1 mg to be ineffective in postmenopausal women with female pattern hair loss at 12 months. However, higher doses of finasteride daily can be effective in cases of female pattern hair loss associated with hyperandrogenemia.

**Side effects.** In a systematic review, the only adverse effect associated with finasteride treatment was erectile dysfunction, with an absolute increase in risk of approximately 1.5%. Approximately 1 in every 80 men treated with finasteride experiences this side effect. Stopping finasteride generally leads to resolution of erectile dysfunction, but sexual dysfunction can persist in some patients.

**Considerations.** Finasteride can result in lower prostate-specific antigen levels in men, which should be taken into consideration when interpreting laboratory results. Due to hepatic metabolism of finasteride, precautions should be taken with patients with liver disease. With chronic treatment, finasteride may cause mild to moderate elevations in serum liver enzymes, but this is usually self-limiting and rarely requires dose modification or drug discontinuation.

### Dutasteride

Dutasteride, a potent type I and type II 5-alpha reductase inhibitor, is used to treat benign prostatic hyperplasia, but is also prescribed as an off-label treatment for pattern hair loss. A randomized control trial in 416 men with male pattern hair loss demonstrated that dutasteride 2.5 mg was superior to finasteride 5 mg in terms of increasing hair count over 24 weeks. Additionally, a meta-analysis found that finasteride and dutasteride had similar efficacy in treating pattern hair loss.

### Latanoprost, bimatoprost

Latanoprost is a prostaglandin F2 analogue that extends the anagen phase. A double-blind, placebo-controlled, randomized trial in 16 men demonstrated an increase in hair density when latanoprost 0.1% was applied to a small area of the scalp. Bimatoprost is also being investigated as a potential treatment for pattern hair loss.
Ketoconazole, zinc shampoo
Ketoconazole, an antifungal medication that has anti-inflammatory and antiandrogenetic properties, can be used to treat seborrheic dermatitis and dandruff. It was found to reduce inflammation in pattern hair loss and to benefit women with hyperandrogenemia and female pattern hair loss when used as a 2% shampoo.

Over-the-counter zinc-containing shampoos have a similar mechanism of action and therapeutic effect.

Spironolactone
Spironolactone competitively inhibits the androgen receptor and also inhibits ovarian production of androgens. Of the antiandrogen drugs used off-label, it is the one most commonly used. It has been used to treat female pattern hair loss for over 2 decades and has a good safety profile. An open-label trial showed that spironolactone 200 mg daily improved hair regrowth in 44% of patients at 12 months, which was comparable to cyproterone acetate.

Cyproterone acetate
Cyproterone acetate is a progesterone derivative that prevents dihydroxytestosterone from binding to the androgen receptor and inhibits release of follicle-stimulating hormone and luteinizing hormone, thereby reducing testosterone levels. It is available combined with ethynyl estradiol as an oral contraceptive in many countries, but is not approved in the United States.

Platelet-rich plasma
Platelet-rich plasma is an autologous preparation of plasma with platelets, growth factors, and cytokines. It was initially used during hair transplantation procedures, with mixed results. Recently its use by itself has been explored to treat pattern hair loss. Preliminary evidence suggests that platelet-rich plasma may be advantageous in hair regrowth. Side effects include redness and pain at injection site and pinpoint bleeding.

Low-level laser therapy
Low-level laser therapy is an FDA-approved treatment for pattern hair loss. The mechanism by which it improves hair loss is unclear, but it may stimulate follicular stem cells or keratinocytes, increase blood flow, promote mitosis, increase cell metabolism, and have anti-inflammatory effects. Two double-blind, sham device-controlled, randomized trials demonstrated that low-level laser therapy increased hair density over 24 to 26 weeks of treatment, although differences global improvement ratings were not significant in one of the trials.

Microneedling
Rolling fine needles over the skin causes minor physical trauma to the stratum corneum that incites wound healing. A randomized controlled trial demonstrated promising results with microneedling as an adjuvant to drug treatment for pattern hair loss. Side effects of the procedure include pain and pinpoint bleeding.

Cosmetic aids
Nonmedical options allow patients to manage the appearance of thinning hair. Scalp colorants, including powders, lotions, and hair sprays, can reduce the color contrast between the skin and hair, camouflaging the scalp. The scalp can also be covered with wigs, hair extensions, or hair pieces.

Hair transplants
Follicles can be transplanted from an unaffected area of the scalp, commonly the occiput, where there are more than 40 follicular units/cm³, to affected areas to create a permanent improvement in hair coverage. Young patients or patients with vertex involvement are not ideal candidates for this procedure due to the high likelihood of continued progression. A large number of grafts, 1,000 to 2,000 follicles, can be transplanted in a single session. Additional transplantation sessions are generally scheduled at least 6 months apart, as it takes 5 to 6 months for results to be established. Pharmacologic treatment, such as oral finasteride, can be used in conjunction with hair transplantation before and after sessions to prevent hair miniaturization and loss of nontransplanted hair follicles.

DISCLOSURES
The authors report no relevant financial relationships which, in the context of their contributions, could be perceived as a potential conflict of interest.
The psychosocial consequences of androgenetic alopecia:
