Diagnosis and management of pancreatic cystic lesions for the non-gastroenterologist

ABSTRACT

Although most pancreatic cystic lesions do not progress to cancer, they create concern for patients and their primary care physicians. The lack of consensus guidelines on diagnosis and surveillance of these lesions can lead to a management conundrum. We review current guidelines on diagnosis and management.

KEY POINTS

Magnetic resonance cholangiopancreatography with dynamic magnetic resonance imaging is the test of choice for diagnosis and assessment of high-risk or worrisome characteristics in cysts. Pancreatic-protocol computed tomography and endoscopic ultrasonography are suitable options if magnetic resonance imaging is contraindicated.

High-risk clinical and laboratory features include obstructive jaundice, recurrent pancreatitis, elevated serum carbohydrate antigen 19-9, presence of cells demonstrating high-grade dysplasia or neoplasia, and new-onset or worsening diabetes.

Pancreatic cystic lesions with high-risk features and those with a known high risk of malignancy, such as main duct intraductal papillary mucinous neoplasms and solid pseudopapillary tumors, should be referred for surgical excision.

Depending on clinical symptoms, suspected pancreatic cystic lesion type, and the presence of certain high-risk features, the monitoring period might range from 3 months to 2 years.

W

ith the enhanced quality and increased frequency of abdominal cross-sectional imaging, pancreatic cystic lesions (PCLs) are incidentally detected in apparently asymptomatic individuals,1 with a pooled prevalence of up to 8%2. Although most of these lesions do not progress to cancer, their high prevalence and unclear potential for malignancy raise concern for patients and primary care physicians.3–5 Thus, before making management decisions, it is necessary to describe PCLs by combining clinical and imaging data to determine the risk of malignancy. Several organizations have released guidelines6–10 on the diagnosis and surveillance of PCLs, each with subtle distinctions, and none are aimed specifically at primary care physicians. In this review, we present a summary of current guidelines for diagnosis and management.

EPIDEMIOLOGY

The prevalence of PCLs in the general population has not been thoroughly investigated due to the inherent difficulty of examining a typically asymptomatic condition. Due to the increased use of abdominal imaging and developments in high-resolution cross-sectional imaging,11 the prevalence of PCLs has gradually increased over the past 10 years.12 Depending on the imaging modality used, the proportion of incidentally discovered PCLs ranges from 0.2% to 45.9%, with a pooled prevalence of 8%.2,5,13 The estimated prevalence also varies according to geographical region, with an estimated frequency of 12.6% in the United States and...
South America, 8.6% in Europe, and 3.1% in Asia.\textsuperscript{2} In general, the incidence of PCLs normally increases with age. However, certain PCLs demonstrate a higher propensity to develop in either females or males, as well as at specific ages or in particular locations within the pancreas.\textsuperscript{2,14}

\section*{PCL CLASSIFICATION}

PCLs are categorized as benign or neoplastic. Benign PCLs include simple cysts, lymphoepithelial cysts, and retention cysts. Neoplastic PCLs include serous cystic neoplasms, solid pseudopapillary tumors, mucinous cystic neoplasms, intraductal papillary mucinous neoplasms, cystic pancreatic endocrine neoplasms, and pancreatic adenocarcinomas with a cystic component.\textsuperscript{2,14–18}

\textbf{Benign PCLs}

Simple cysts (also known as true epithelial cysts) are unilocular, lined by a single epithelial layer, have no communication with the pancreatic ductal system, and have no malignant potential.\textsuperscript{16} Lymphoepithelial cysts are more common in males in their 50s and are observed throughout the pancreas. They are sometimes mistaken for pseudocysts and have a mean size of 5 cm, and around half of them are multilocular.\textsuperscript{17,18} Retention cysts are dilated side branches of the pancreatic duct produced by blockage (eg, calculi, mucin), and they may have mucinous mucosal lining and can be difficult to differentiate from intraductal papillary mucinous neoplasms, PCLs with malignant potential.\textsuperscript{19} In some classification schemes, acute pancreatic fluid collection, pseudocyst, acute necrotic collection, and walled-off necrosis are considered benign inflammatory fluid collections, but these are not true PCLs because the contents are not lined by epithelial cells and the lesions are not always found in the pancreas.

\textbf{Neoplastic PCLs}

Table 1 lists the key epidemiologic, clinical, and imaging characteristics of neoplastic PCLs.

Data from references 6–10, 19.
Mucinous cysts are lined with a mucin-producing epithelium and include intraductal papillary mucinous neoplasms.6 The difference between mucinous cystic neoplasms and intraductal papillary mucinous neoplasms is the presence of a connection to the pancreatic ductal system. Mucinous cystic neoplasms do not communicate with the ductal system, whereas intraductal papillary mucinous neoplasms originate from the ductal system.9,20

Mucinous cystic neoplasms are found in the body and tail of the pancreas and are almost exclusively found in women ages 40 to 60 (with a peak incidence at age 40 to 50). These neoplasms have a characteristic ovarian-type stroma and have been found to be malignant in 0% to 34% of cases.20,21

Intraductal papillary mucinous neoplasms are divided into 3 types: main duct type, branch duct type, and mixed type. The mixed type involves the main duct and the branch duct, based on imaging studies with or without histology. Main duct intraductal papillary mucinous neoplasms cause dilation of the main pancreatic duct of more than 5 mm without other identified causes. Branch duct intraductal papillary mucinous neoplasms have a lower risk of malignancy, ranging between 12% and 47%, while main duct intraductal papillary mucinous neoplasms and mixed type have a higher risk of being malignant, ranging from 38% to 68%.22

Serous cystic neoplasms are most frequent in women between the ages of 50 and 60, exhibit a honeycomb appearance on imaging (many tiny cysts surrounding a central stellate scar with calcification), and have a negligible chance of becoming malignant.22,23 There are 4 distinct morphological patterns: microcystic, macrocystic, mixed microcystic and macrocystic, and solid.23,24

Solid pseudopapillary tumors are large solid, cystic, or mixed solid-cystic tumors that primarily affect young women. Although their malignant potential has not been well investigated, these are certainly malignant tumors with both local and metastatic potential, and surgical excision is recommended.25

Other lesions with a cystic appearance include pancreatic adenocarcinomas with a cystic component and cystic pancreatic endocrine neoplasm.7,26

## PCL CANCER RISK

Determining the cancer risk of PCLs should be approached in 2 steps. First, determine whether the cyst is neoplastic. Next, look for clinical and imaging signs that have been linked to an elevated risk of cancer and are described as “high-risk” or “worrisome” characteristics.6

High-risk clinical features include obstructive jaundice without other explanation, recurrent pancreatitis due to a PCL, a significantly elevated serum carbohydrate antigen 19-9 level, or, if cytology is obtained, the presence of cells demonstrating high-grade dysplasia or neoplasia, and new-onset or worsening diabetes. Worrisome characteristics include main pancreatic duct dilation greater than or equal to 5 mm, cyst size greater than or equal to 3 cm, and the presence of a solid component or mural nodule in the PCL.6,7,9,10 Of the PCLs with malignant potential, mucinous cystic neoplasms and intraductal papillary mucinous neoplasms are the most commonly observed in clinical practice.

Table 2 lists the high-risk and worrisome traits for presumed intraductal papillary mucinous neoplasms. When 1 or more of these characteristics are present, the patient should be referred to a center of excellence for additional examination and treatment by a multi-disciplinary expert group.

### DIAGNOSIS

PCLs are frequently seen on cross-sectional imaging of the abdomen in asymptomatic patients. If a PCL is an incidental finding, dedicated magnetic resonance cholangiopancreatography with dynamic magnetic resonance imaging is the test of choice and should be
Figure 1. Strategy to evaluate and manage pancreatic cystic lesions.

1. Pancreatic cystic lesion found on cross-sectional abdominal imaging (If the patient has a history of pancreatitis, evaluate for pseudocyst)

2. Does the patient have symptoms or high-risk cyst features such as obstructive jaundice, enhancing mural nodule ≥ 5 mm, or main pancreatic duct dilation ≥ 10 mm? If no to all of the above and if the cyst is < 3 cm, consider observation (refer to Table 3)

   - Yes, but resection is not appropriate

   - Perform endoscopic ultrasonography and fine-needle aspiration with cyst fluid analysis and cytology studies to distinguish between serous or mucinous cysts

3. Serous cystadenoma:
   - Mucin-negative
   - Carcinoembryonic antigen < 5 ng/mL

4. Mucinous cyst:
   - Mucin-positive
   - Carcinoembryonic antigen > 192 ng/mL

5. Does the patient have any of these worrisome features for malignancy?
   - Positive or suspicious cyst fluid cytology
   - Thickened cyst wall
   - Cyst size ≥ 3 cm
   - Higher levels of carbohydrate antigen 19-9
   - Change in the caliber of the pancreatic duct with distal pancreatic atrophy

   - Yes

6. Does the cyst communicate with the main pancreatic duct?
   - Yes
   - Consider intraductal papillary mucinous neoplasm
   - Observe with computed tomography or magnetic resonance imaging at regular intervals (refer to Table 3)

   - No
   - Consider mucinous cystic neoplasm

7. Mural nodule > 5 mm
   - Main pancreatic duct dilation of 5–9 mm
   - New-onset diabetes
   - Lymphadenopathy

   - Yes

8. Consider resection in young patients who may prefer surgery to extended surveillance
performed to identify the cyst characteristics and any high-risk or worrisome characteristics.6–8

In patients who are unable to undergo magnetic resonance imaging, pancreatic-protocol computed tomography and endoscopic ultrasonography are suitable options.7 If the diagnosis is ambiguous, or if the PCL has clinical or radiologic worrisome features, endoscopic ultrasonography can give further diagnostic information.3 Fine-needle aspiration for cystic fluid cytology and biomarker analysis can provide information on amylase concentration, intracystic glucose level, carcinoembryonic antigen levels, or molecular markers.7,27,28 Notably, while certain PCLs can be accurately diagnosed using cross-sectional imaging with or without endoscopic ultrasonography with fine-needle aspiration for cytology, surgical pathology is required for definitive histologic classification.29

Lately, remarkable progress has been made in the identification and validation of molecular cyst fluid biomarkers such as KRAS, GNAS, SPINK1, interleukin-1-beta, cancer antigen 72-4, vascular endothelial growth factor-A, vascular endothelial growth factor receptor 2, prostaglandin E2, and methylated DNA biomarkers. These biomarkers play a pivotal role in aiding the diagnostic process, contributing to improved accuracy in assessing PCLs.

**Management and Prognosis**

PCLs that have the potential to become malignant are managed by active monitoring or surgical excision. PCLs with high-risk characteristics, and those with a known high risk of malignancy, such as main duct intraductal papillary mucinous neoplasms and solid pseudopapillary tumors, should be referred for surgical excision. Patients with PCLs who have symptoms such as pancreatitis, nausea and vomiting caused by intestinal obstruction, or abdominal discomfort should undergo surgical evaluation regardless of cancer risk.

Patients with asymptomatic cysts and those without high-risk characteristics can undergo active surveillance, as the likelihood of advanced neoplasia is low. Surveillance is not advised for people older than 85 or people with too many medical comorbidities to undergo surgery. Simple cysts and asymptomatic pseudocysts don’t require monitoring. Depending on clinical symptoms, suspected PCL type, and the existence of high-risk traits, the monitoring period might range from 3 months to 2 years.

Due to its exceptional resolution and ability to discern the main pancreatic duct effectively, magnetic resonance imaging and magnetic resonance cholangiopancreatography are used for surveillance. On the other hand, endoscopic ultrasonography is reserved for patients displaying concerning characteristics, in addition to fine-needle aspiration of cyst fluid for a precise diagnosis through biomarker analysis. However, for lesions with no worrisome features, a combination of history, examination, and radiologic characteristics may commonly define the type of PCL and assess the risk of malignant degeneration. Figure 1 outlines a strategy to evaluate and manage PCLs.

The duration of PCL surveillance is debatable, with most current guidelines recommending the surveillance interval based on radiologic PCL appearance and changes over time compared with previous imaging, while some advocate stopping after 5 years if the PCL is stable and has not progressed. If the patient is unwilling to undergo pancreatic surgery or is unfit for surgery, then asymptomatic PCL surveillance may be stopped as it is unlikely to impact clinical management or survival.

Experts advocate maintaining surveillance till age 75 and individualizing follow-up between ages 76 and 85 (Table 3). It is also advised to inform patients that they may require continued surveillance even after undergoing partial pancreatic resection, as recurrence may occur in the remnant pancreas. Although it is difficult to find strong prospective evidence that surveillance reduces mortality, studies have shown that PCLs with the potential to become malignant can take years to develop, and that pancreatic cancers detected through surveillance were more frequently at an earlier stage in patients with intraductal papillary mucinous neoplasms.

**Conclusion**

Pancreatic cysts are frequently found incidentally on cross-sectional imaging. The possibility of malignancy varies depending on the type of PCL. Magnetic resonance cholangiopancreatography with dynamic magnetic resonance imaging is the preferred test to identify cyst characteristics and high-risk or worrisome features. PCLs with malignant potential are treated by close surveillance or surgical excision. A multidisciplinary team should assess PCLs with high-risk characteristics and those with a known high risk of malignancy, such as main duct intraductal papillary mucinous neoplasms, mucinous cystic neoplasms, and solid pseudopapillary tumors.

Because advanced neoplasia is unlikely, active surveillance is appropriate for asymptomatic cysts and those that do not have any high-risk characteristics. Surgery should be performed to remove high-risk PCLs or those that progress while under surveillance. The overall prognosis is favorable, with early detection and active surveillance serving as the cornerstones of management.
